Detecting Ransomware Addresses on the Bitcoin Blockchain using Random Forests and Self Organizing Maps

HarvardX PH125.9x Final Capstone CYO Project

Kaylee Robert Tejeda

10/31/2021

Abstract

Ransomware is a persisent and growing threat in the world of cybersecurity. A specific area of focus involves detecting and tracking payments made to ransomware operators. While many attempts towards this goal have not made use of sophisticated machine learning methods, even those that have often result in models with poor precision or other performance issues. A two-step method is developed to address the issue of false positives and improve on previous results.

Introduction

Ransomware attacks have gained the attention of security professionals, law enforcement, and financial regulatory officials.^[1] The pseudo-anonymous Bitcoin network provides a convenient method for ransomware attackers to accept payments without revealing their identity or location. The victims (usually hospitals or other large organizations) come to find that much if not all of their important organizational data have been encrypted with a secret key by an unknown attacker. They are instructed to make a payment to a specific Bitcoin address before a certain deadline to have their data decrypted before being deleted permanently.

The legal and financial implications of ransomware attacks are not of concern for the purpose of this analysis. Many parties are interested in tracking illicit activity (such as ransomware payments) around the Bitcoin blockchain as soon as possible to minimize financial losses. Daniel Goldsmith explains some of the reasons and methods of blockchain analysis at Chainalysis.com.^[2] A ransomware attack could be perpetrated on an illegal darknet market site, for example. The news of such an attack might not be published at all, let alone in popular media. By analyzing the transaction record with a blockchain explorer such as BTC.com, suspicious activity could be flagged in real time given a sufficiently robust model. It may, in fact, be the first public notice of such an event. Any suspicious addresses could then be blacklisted or banned from using other services.

Lists of known ransomware payment addresses have been compiled and analyzed using various methods. One well known paper entitled "BitcoinHeist: Topological Data Analysis for Ransomware Detection on the Bitcoin Blockchain"^[3] will be the source of our data set and the baseline to which we will compare our results. In that paper, Akcora, et al. use Topological Data Analysis (TDA) to classify addresses on the Bitcoin blockchain into one of 28 known ransomware address groups. Addresses with no known ransomware associations are classified as "white". The blockchain is then considered as a heterogeneous Directed Acyclic Graph (DAG) with two types of nodes describing *addresses* and *transactions*. Edges are formed between the nodes when a transaction can be associated with a particular address.

Addresses on the Bitcoin network may appear many times, with different inputs and outputs each time. The Bitcoin network data has been divided into 24-hour time intervals with the UTC-6 timezone as a reference. Speed is defined as the number of blocks the coin appears in during a 24-hour period and provides information on how quickly a coin moves through the network. Speed can be an indicator of money laundering or coin mixing, as normal payments only involve a limited number of addresses in a 24 hour period, and thus have lower speeds when compared to "mixed" coins. The temporal data can also help distinguish transactions by geolocation, as criminal transactions tend to cluster in time.

With the graph defined as such, the following six numerical features^[2] are associated with a given address:

- 1) Income the total amount of coins sent to an address (decimal value with 8 decimal places)
- 2) Neighbors the number of transactions that have this address as one of its output addresses (integer)
- 3) Weight the sum of fraction of coins that reach this address from address that do not have any other inputs within the 24-hour window, which are referred to as "starter transactions" (decimal value)
- 4) Length the number of non-starter transactions on its longest chain, where a chain is defined as an acyclic directed path originating from any starter transaction and ending at the address in question (integer)
- 5) Count The number of starter addresses connected to this address through a chain (integer)
- 6) Loop The number of starter addresses connected to this address by more than one path (integer)

These variables are defined rather abstractly, viewing the blockchain as a topological graph with nodes and edges. The rationale behind this approach is to quantify specific transaction patterns. Akcora^[3] gives a thorough explanation in the original paper of how and why these features were chosen. We shall treat the features as general numerical variables and will not seek to justify their definitions. Several machine learning methods will be applied to the original data set from the paper by Akcora^[3], and the results will be compared.

Data

This data set was discovered while exploring the UCI Machine Learning Repository^[4] as suggested in the project instructions. The author of this report, interested in Bitcoin and other cryptocurrencies since (unsuccessfully) mining them on an ASUS netbook in rural Peru in late 2010, used *cryptocurrency* as a preliminary search term. This brought up a single data set entitled "BitcoinHeist: Ransomware Address Data Set". The data set was downloaded and the exploration began.

This data set has 2,916,697 observations of ten features associated with a sample of transactions from the Bitcoin blockchain. The ten features include *address* as a unique identifier, the six features defined previously (*income, neighbors, weight, length, count, loop*), two temporal features in the form of *year* and *day* (of the year as 1 to 365), and a categorical feature called *label* that categorizes each address as either "white" (meaning not connected to any ransomware activity), or one of 28 known ransomware groups as identified by three independent ransomware analysis teams (Montreal, Princeton, and Padua)^[3].

The original research team downloaded and parsed the entire Bitcoin transaction graph from January 2009 to December 2018. Based on a 24 hour time interval, daily transactions on the network were extracted and the Bitcoin graph was formed. Network edges that transferred less than B0.3 were filtered out since ransom amounts are rarely below this threshold. Ransomware addresses are taken from three widely adopted studies: Montreal, Princeton and Padua. "White" Bitcoin addresses were capped at one thousand per day while the entire network has up to 800,000 addresses daily.^[5]

Goal

The goal of this project is to apply different machine learning algorithms to the same data set used in the original paper to produce an acceptable predictive model for categorizing ransomware addresses correctly. Improving on the results of the original paper in some way, while not strictly necessary for the purposes of the project, would be a notable sign of success.

Outline of Steps Taken

- 1) Analyze data set numerically and visually. Notice any pattern, look for insights.
- 2) Binary separation using Self Organizing Maps.
- 3) Improved Binary separation using Random Forests.
- 4) Categorical classification using Self Organizing Maps.

- 5) Visualize clustering to analyze results further.
- 6) Generate Confusion Matrix to quantify results.

Data Analysis

Hardware Specification

All of the analysis in this report was conducted on a single laptop computer, a Lenovo Yoga S1 from late 2013 with the following specs:

- CPU: Intel i7-4600U @ 3.300GHz (4th Gen quad-core i7)
- RAM: 8217MB DDR3L @ 1600 MHz (8 GB)
- OS: Slackware64-current (15.0 RC1) x86_64-slackware-linux-gnu (64-bit GNU/Linux)
- R version 4.0.0 (2020-04-24) "Arbor Day" (built from source using scripts from slackbuilds.org)
- RStudio Version 1.4.1106 "Tiger Daylily" (2389bc24, 2021-02-11) for CentOS 8 (converted using rpm2tgz)

Data Preparation

It is immediately apparent that this is a rather large data set. The usual practice of partitioning out eighty to ninety percent of the data for a training set results in a data set that is too large to process given the hardware available. For reasons that no longer apply, the original data set was first split in half with 50% reserved as "validation set" and the other 50% used as the "working set". This working set was again split in half, to give a "training set" that was of a reasonable size to deal with. At this point the partitions were small enough to work with, so the sample partitions were not further refined. This is a potential area for later optimization. Careful sampling was carried out to ensure that the ransomware groups were represented in each sample.

Exploration and Visualization

The ransomware addresses make up less than 2% of the overall data set. This presents a challenge as the target observations are sparse within the data set, especially when we consider that this is then divided into 28 subsets. In fact, some of the ransomware groups have only a single member, making categorization a dubious task. At least there are no missing values to worry about.

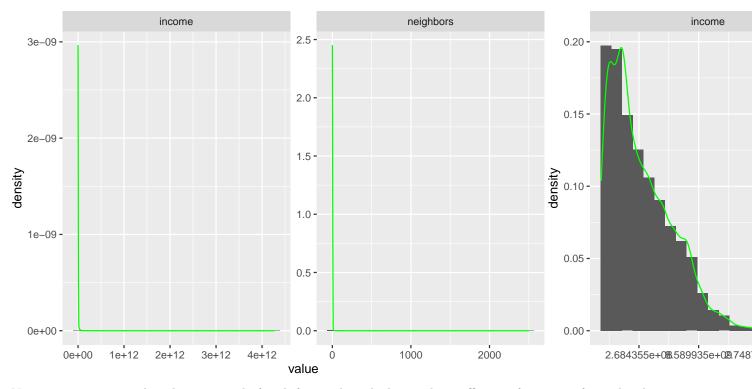

The proportion of ransomware addresses in the original data set is 0.0141985951917529.

The total number of NA or missing values in the original data set is 0.

Let's take a look at the distribution of the different features. Note how skewed the non-temporal features are, some of them being bimodal:

	х		х
montrealAPT	11	montrealRazy	13
montrealComradeCircle	1	montrealSam	1
montrealCryptConsole	7	montrealSamSam	62
montrealCryptXXX	2419	montrealVenusLocker	7
montreal CryptoLocker	9315	montrealWannaCry	28
montreal Crypto Tor Locker 2015	55	montreal XLocker	1
montrealDMALocker	251	montrealXLockerv5.0	7
montrealDMALockerv3	354	montreal XTPLocker	8
montrealEDA2	6	paduaCryptoWall	12390

montrealGlobev3	34	princetonLocky	6625
montreal Jig Saw	4	white	2875284
montrealNoobCrypt	483		

Table 4: Ransomware group labels and frequency counts for full data set

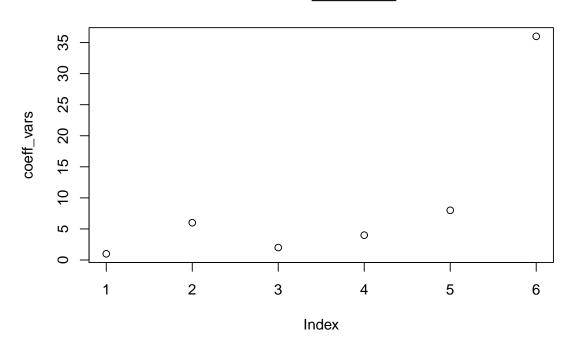

Now we can compare the relative spread of each feature by calculating the coefficient of variation for each column. Larger coefficients of variation indicate larger relative spread compared to other columns.

The features with the highest coefficients of variation are incomeneighbors, which will be used to train

	х
length	1
weight	6
count	2

	х
looped	4
neighbors	8
income	36

From this, it appears that *income* has the widest range of variability, followed by *neighbors*. These are also the features that are most strongly skewed to the right, meaning that a few addresses have really high values for each of these features while the bulk of the data set has very low values for these numbers.

Now do the following (after filling in methods, results, and conclusions, since those are done already):

6) Break into groups somehow. Graph variables per group? Show how the variables are distributed for each ransomware group? Percent ransomware per each day of the week, for example. Is ransomware more prevalent on a particular day of the week? Break other numerical values into bins, and graph percentage per bin. Look for trends and correlations between groups/variables, and display them here. MORE OF THIS....

[1] 0.01224662

Insights Gained from Exploration

From the previous visual and statistical exploration of the data, it becomes clear what the challenge is. Ransomware related addresses are very sparse in the data set, making up less than 2% of all addresses. That small percentage is also further classified into 28 groups. Perhaps the original paper was a bit too ambitious in trying to categorize all the addresses into 29 categories, including the "white" addresses. To simplify our approach, we will categorize the addresses in a binary way, either "white" or "black", where "black" signifies an association with ransomware transactions. Asking this as a "ransomware or not-ransomware" question allows for application of methods that are known to be impractical otherwise.

Modeling approach

Akcora et al. applied a Random Forest approach to the data, however "Despite improving data scarcity, [...] tree based methods (i.e., Random Forest and XGBoost) fail to predict any ransomware family".[3, 11] Considering all ransomware addresses as belonging to a single group might improve the predictive power of such methods, making Random Forest worth another try.

The topological description of the data set inspired a search for topological machine learning methods, although one does not necessitate the other. Searching for *topo* in the documentation for the **caret** package [6] resulted in the entry for Self Organizing Maps, supplied by the **kohonen** package. The description at CRAN [7] was intriguing enough to merit further investigation.

Initially, the categorization of ransomware into the 28 different families was attempted using SOMs. This proved to be very resource intensive, requiring more time and RAM than was available at the time. Although it did help to illuminate how SOMs are configured, the resource requirements of the script became a deterrent. It was at this point that the SOMS were applied in a binary way, classifying all ransomware addresses as merely "black". This seemed to reduce RAM usage to the point of being feasible on the available hardware.

Being unsure of the SOM method, since it was not covered in the coursework at any point, a familiar method was sought out to compare the results to. This is when Random Forest was applied to the data set in a binary way. Much to the surprise of the author, not only did the Random Forest approach result in an acceptable model, it surpassed the model produced by the SOM approach.

The author was tempted to leave it there and write up a comparison of the two approaches to the binary problem. However, a nagging feeling that more could be done eventually inspired a second look at the categorical problem of categorizing the ransomware addresses into the 28 families. Given the high accuracy and precision of the Random Forest approach to the binary problem, it became apparent that the sparseness of the ransomware in the larger set had been eliminated completely, as had any chances of false positives. There are a few cases of false negatives, depending on how the randomization is done during the sampling process. However, the Random Forest method has never produced a false positive yet, meaning it never seems to predict a truly white address as being black. Hence, by applying the Random Forest method first, we have essentially filtered out any possibility of false positives, which is exactly what plagued the original paper by Akcora et al.[3]

Finally, a two-part method was devised to first separate the addresses into black and white groups, and then further classify the black addresses into ransomware families. Let's explore each of these separately.

Method Part 0: Binary SOMS as a first attempt to isolate ransomware addresses.

Lets see how well the SOM approach can model the data in a black/white fashion.

Here are some graphs, but be careful with these....

Here are the results of the binary SOM model.

	black	white
black	10349	0
white	0	718803
		1.1.
	black	white
black	20699	0
white	1	1437607
-		

This winds up being the most resource intensive and least accurate method out of those tried. It was left out of the final version of the script and is not really worth running except to compare to the next method.

Method Part 1: Binary Random Forests to isolate ransomware addresses before categorization.

A Random Forest model is trained using ten-fold cross validation and a tuning grid with the number of variables randomly sampled as candidates at each split mtry set to the values = 2, 4, 6, 8, 10, 12, each one being checked for optimization.

The confusion matrix for the test set shows excellent results, specifically in the areas of accuracy and precision.

Method Part 2: Categorical SOMs to categorize predicted ransomware addresses.

Now we train a new model after throwing away all "white" addresses. The predictions from the Random Forest model are used to isolate all "black" addresses for further classification into ransomware addresses using SOMs.

When selecting the grid size for a Self Organizing Map, there are at least two different schools of thought. The two that were tried here are explained (with supporting documentation) on a Researchgate forum.[8] The first method is based on the size of the training set, and in this case results in a larger, more accurate map. The second method is based on the number of known categories to classify the data into, and in this case results in a smaller, less accurate map. For this script, a grid size of 27 has been selected.

A summary of the results for the categorization of black addresses into ransomware families follows. For the full table of predictions and statistics, see the Appendix.

Clustering Visualizations: K-means clustering

K-means clustering offers a nice way of visualizing the final SOM grid and the categorical boundaries that were formed by the model.

K-means clustering categorizes the SOM grid by adding boundaries to the classification groups. This is the author's favorite graph in the entire report.

Results & Performance

Results

The first attempt to isolate ransomware using SOMs resulted in a model with an accuracy of 0.999999314273332 and precision 1.

The the second attempt to isolate ransomware using Random forest resulted in a model with an accuracy of 0.999963657520819 and precision 1.

Classifying the ransomware predicted by the second attempt into 28 ransomware families resulted in a model with an overall accuracy of 0.996900426191399 and minimum nonzero precision of 0.25.

Performance

The script runs on the aforementioned hardware in less than five minutes and uses less than 4GB of RAM. Given that the Bitcoin network produces one new block every ten minutes on average, then real-time analysis could theoretically be conducted on each block as it is announced using even moderate computing resources. Just for kicks, the final script was also run on a more humble computer with the following specifications:

- CPU: Intel Atom N2600 @ 1.600GHz (64-bit Intel Atom quad-core)
- RAM: 3911MB DDR3 @ 800 MT/s (4 GB)

This is a computer known for being slow and clunky. Even on this device, which runs the same operating system and software as the hardware listed previously, the total run time for the script is around 1665 seconds. At nearly 28 minutes, this is not fast enough to analyze the Bitcoin blockchain in real time, but it does show that the script can be run on very modest hardware to completion.

Summary

Comparison to results from original paper

In the original paper by Akcora et al., they tested several different sets of parameters on their TDA model. According to them, "In the best TDA models for each ransomware family, we predict **16.59 false positives for each true positive**. In turn, this number is 27.44 for the best non-TDA models."[3] In fact, the highest Precision (a.k.a. Positive Predictive Value, defined as TP/(TP+FP)) they achieved was only 0.1610. By comparison, although several of our predicted classes had zero or NA precision values, the lowest non-zero precision value is 0.25, with many well above that, approaching one in a few cases.

One might say that we are comparing apples to oranges in a sense, because their method was one single model, while these results are from a two-method stack. Still, given the run time of the final script, I think the two-model approach is superior in this case, especially when measured in terms of precision and avoiding false positives.

Limitations

SOMs seem like they are easy to misconfigure. Perhaps a dual Random Forest approach would be better. this has not been attempted yet, as the two method approach presented here was satisfactory enough to present in a report.

Future Work

I only scratched he surface of the SOM algorithm which seems to have many implementations and parameters that could be investigated further and possibly optimized via cross-validation. Also, a dual Random Forest approach to first isolate the ransomware addresses and also

The script itself has a few areas that could be further optimization. The sampling method does what it needs to do, but the ratios taken for each set could possibly be optimized.

Conclusion

This paper/report presents a reliable method for classifying Bitcoin addresses into known ransomware families, while at the same time avoiding false positives by filtering them out using a binary method before classifying them further. It leaves the author of the paper wondering how much harder it would be to perform the same task for ransomware that uses privacy coins. Certain cryptocurrency networks utilize privacy coins, such as Monero, that obfuscate transactions from being analyzed in the same way that the Bitcoin network has been analyzed here. Some progress has been made towards analyzing such networks[9], but the developers of such networks continually evolve the code to complicate transaction tracking. This could be another good area for future research.
